

Segmented Regression via the Shape Language Modeling for Multi-Slope Path-Loss Modeling

Dayan Adionel Guimarães

Abstract—The multi-slope law for the area-mean received signal power decay has been considered a more adequate choice for modeling and analyzing the propagation path-loss in wireless networks. This paper presents a method for fitting local-mean signal power measurements to a non-increasing, two- or three-slope piece-wise linear function of the transmitter-receiver distance. The optimal fit is achieved by means of the shape language modeling (SLM) tool when configured to the first order spline fitting option, with two and three segments. Some results are presented and discussed, and guidelines are given in what concerns the strategy for sampling the received power levels.

Keywords—Multi-slope path-loss, segmented regression, shape language modeling.

I. INTRODUCTION

Planing and deploying wireless communication systems often demand accurate knowledge of the environment-dependent signal propagation characteristics, mainly in terms of large-scale path-loss. Path-loss knowledge is crucial for determining placement and coverage of base stations, and for optimizing the network. To this end, there are numerous propagation models available [1]–[5], some of them adopted by software packages known as wireless network planning tools [6] for coverage (or propagation) prediction. Many propagation prediction models are derived from, or are based on the well-known log-distance path-loss model [7], for instance the Stanford University Interim (SUI) [8], [9]. The log-distance model states that the area-mean received power decays linearly with the logarithm of the transmitter-receiver distance, with a slope determined by the environment morphology and topography. Other equally simple models dictate that the distance-dependent area-mean received signal power decays following more than one slope. This is the case of the classic plane-earth two-ray model [10], in which the received signal power decay obeys a two-slope law whose breakpoint (where the slopes change inclination) lies at the location where the first Fresnel zone touches the ground [11].

Recently, the two-slope law and its multi-slope generalization have been put into focus, for instance in [12], where it has been demonstrated that the capacity and throughput analysis of a wireless network can be severely impacted if such a model is adopted, resulting in conclusions that significantly depart from those in which the conventional single-slope law is considered.

This is specially true in dense networks, e.g. in the fifth-generation (5G) cellular systems, and Internet of things (IoT) and sensor networks with close apart nodes. The particular case of the dual-slope model has been shown to adhere to measurements in indoor [13] and outdoor [14]–[16] environments. In [17], a multi-slope fit from measured data has been proved to be suitable for path-loss modeling of the on-body channel, in the context of wireless body networks. The authors of [18] present experimental propagation measurements over the sea at 5.8 GHz, concluding that a multi-slope model is more appropriate than traditional models that use only one slope for non-line-of-sight transmissions. The signal power decay is modeled in [19] by a dual-breakpoint (three slopes) model as a function of the distance between a transmitter and an on-body sensor, and as a function of the body orientation angle for ultrawideband off-body communication channels in the frequency range between 3.5 and 6.5 GHz. In [20], the connection probability in vehicle-to-vehicle communications in urban scenarios is analyzed based on a dual-slope path-loss model. A ray-tracing based dual-slope model is proposed in [21] and claimed to be appropriate for evaluating the performance of millimeter-wave (mmWave) systems in dense urban environments. In [22], the influence of a dual-slope path-loss model on the problem of user association in heterogeneous networks is investigated. A study about the capacity of cooperative vehicular ad hoc networks under a measurement-based dual-slope path-loss model is reported in [23]. Area-mean path-loss breakpoints were also observed in several test scenarios in a campaign based on mobile-to-mobile channel measurements at 1.85 GHz in dense-scattering suburban environments [24]. A recently-proposed model for the mmWave range also considers a two-slope path loss [25].

A. Problem statement and typical solutions

In the multi-slope path-loss model, the loss exponent associated to each slope and the breakpoints are derived from measured received powers, based on the log-distance model. However, this is not a trivial task because of the problem constraints: i) the area-mean received power must be a continuous function of the distance, by the nature of the distance-dependent path-loss model. In other words, it is not expected that a propagation mechanism would produce discontinuities in the function that describes the variation of the area-mean received power with distance; ii) if the breakpoints of the multiple slopes were known, which is not reasonable to assume in practice, the application of the ordinary least squares (OLS) linear regression on the data set associated to each segment

would result in a better fitting for each slope alone, but would produce discontinuities at the breakpoints and an overall useless regression result; iii) in a multi-slope model, it is common to consider that the first breakpoint appears at the distance from the transmitter in which the first Fresnel zone touches the ground. However, the actual first breakpoint distance may depart from the theoretical, since the presence of obstacles can move the touching point of the Fresnel zone to a distance closer to the transmitter. More breakpoints might show up in nondeterministic positions, depending on the particularities of each area under analysis. As a consequence, breakpoints often cannot be determined theoretically.

Typical approaches for solving the problem of multi-slope path-loss regression can resort to optimization techniques, for instance the ones adopted in [26]–[28], or to specialized software tools. In [26], a general approach of convex regression with adaptive classification is considered, and [27] applies particle swarm optimization (PSO) to the case of a multi-slope path-loss model. In terms of software packages, the shape language modeling (SLM) [28] is a versatile curve fitting tool based on least squares splines, which can be configured with first-order spline and other simple constraints to yield a piece-wise linear regression to input data. The SLM is implemented in Matlab and makes use of the Matlab optimization toolbox. The Origin package [29], which is a data analysis and graphing software application, has two-slope and three-slope built-in linear piece-wise fitting options. Another software tool for segmented regression is the joinpoint regression program (Joinpoint) [30], which has been developed to test whether or not an apparent change in a trend is statistically significant. The Joinpoint can also be applied to the multi-slope regression problem, but, likewise the Origin tool, its integration with automated analysis is not possible, owed to the lack of programming facilities similar to the Matlab.

B. Contribution and organization of the paper

This paper presents a method for gathering received signal power measurements and fitting the local-mean powers to a multi-slope path-loss model, using the SLM tool. Especial attention is paid to the fitting (or regression) process, since it is the most critical from the model parameterization standpoint. Besides simulated measurements and fitting results, the paper also provides guidelines for helping engineers and researchers to perform actual power measurements. Section II presents the multi-slope model. Sampling methods and the multi-slope regression are addressed in Section III. Section IV is devoted to numerical results and discussions, and Section V concludes the paper.

II. MULTI-SLOPE PATH-LOSS MODEL

The multi-slope model is grounded on the two-ray plane earth model [10], or simply two-ray model, which has been found in [11] to suitably represent the signal attenuation in real scenarios departing from the idealized assumptions of the model. In this model, transmitter and receiver are in line-of-sight condition and lay on a plane-earth surface such that a reflected path towards the receiver is formed. Two path-loss

regions separated by a breakpoint can be distinguished: before the breakpoint, the received signal power varies severely due to destructive and constructive combination between the direct and the reflected rays, whereas after the breakpoint it decreases linearly with the log-distance [11]. The breakpoint is at the distance d_c , from the transmitter, in which the first Fresnel zone touches the ground. This distance, often referred to as the critical distance [12], [15], is given by $d_c \approx 4h_t h_r / \lambda$, where h_t is the transmitting antenna height, h_r is the receiving antenna height, and λ is the carrier wavelength, all in meters.

In urban areas, the breakpoint might happen closer to the transmitter due to the presence of obstacles that hit the first Fresnel zone in a distance that might be far below d_c [15], [16]. In such environments, the first breakpoint may be at, or even before the distance [16, eq. (2)]

$$d_{bp} = \frac{4(h_t - h_{avg})(h_r - h_{avg})}{\lambda}, \quad (1)$$

where $h_{avg} < h_r$ is the average height of obstacles between the transmitter and the receiver. For suburban areas, this average height is typically in the range of 6 to 15 m [31]–[34], and for dense urban areas it typically lies in the range of 30 to 40 m [32], [33], [35].

More than one breakpoint may show-up from measured data [13]–[16], which gives rise to the multi-slope model [12]. In the case of three slopes, which can be readily specialized to any number of slopes, the area-mean received signal power, in dBm, at a distance d from the transmitter, is given by

$$P(d) = \begin{cases} P(d_0) - 10n_1 \log\left(\frac{d}{d_0}\right), & d \leq BP_1 \\ P(d_0) - 10n_2 \log\left(\frac{d}{d_0}\right) + \Delta_1, & BP_1 < d < BP_2 \\ P(d_0) - 10n_3 \log\left(\frac{d}{d_0}\right) + \Delta_1 + \Delta_2, & d \geq BP_2 \end{cases}, \quad (2)$$

where n_1 , n_2 and n_3 are dimensionless loss exponents, BP_1 and BP_2 are the breakpoints, in meters, and $P(d_0)$ is the area-mean received power, in dBm, at a reference unobstructed distance d_0 from the transmitter, in meters, $\lambda \ll d_0 < d_c$. For example, using the simplified form of the Friis equation, $P(d_0) = 10 \log [P_t G_t G_r (\lambda / 4\pi d_0)^2]$ dBm, where P_t is the transmit power delivered to the antenna, in milli-watts (mW), and G_t and G_r are the transmit and receive antenna dimensionless gains, respectively. Notice that this choice of d_0 contrasts with the value of $d_0 > d_c$ that is typically assumed in the conventional single-slope regression, a case in which d_0 must be placed after the first breakpoint that is typically considered to be at the critical distance. In such a case, the value of $P(d_0)$ is often determined from a single measurement of the area-mean received power at a reference distance $d_0 > d_c$.

The constants Δ_1 and Δ_2 in (2) guarantee that successive slopes join at the breakpoints, and are given by

$$\Delta_1 = 10(n_2 - n_1) \log\left(\frac{BP_1}{d_0}\right), \quad (3)$$

$$\Delta_2 = 10(n_3 - n_2) \log\left(\frac{BP_2}{d_0}\right). \quad (4)$$

III. SAMPLING AND SEGMENTED REGRESSION

The characterization of received signal power variations can be made via samples collected during measurement cam-

paings. Since the number of samples n needed to characterize the small-scale multipath fading is much larger than the number N necessary for the analysis of large-scale propagation, here it is assumed that only the N local-mean power measurements are retained, meaning that they describe both the distance-dependent signal attenuation and the power variation caused by obstacles, referred to as shadowing. Multipath fading is removed, which in practice is achieved by filtering instantaneous local measurements, or making measurements of average levels in each location of interest.

Two sampling methods are adopted here: **method 1** considers equally-spaced samples in logarithmic-scaled distances, and **method 2** adopts equally-spaced samples in linear-scaled distances. These methods can be interpreted with the help of Figure 1, where it is shown a hypothetical aerial view of a region of interest for the purpose of propagation analysis. The rectangles represent city blocks and the spaces between them are the streets. The transmitter is supposed to be in the middle block on the left, and instantaneous power measurements are supposed to be made along the path indicated by the solid line passing through some streets. It is assumed that the measurement platform is automated and has the following attributes: i) the measurement vehicle is equipped with a proper signal receiver, a time recorder, a positioning facility, for example a global positioning system (GPS) receiver, and a computer platform to store the measurements; ii) the spacial sampling spacing must be set to allow for capturing the short-term received signal power variations, meaning that the sampling frequency must be automatically varied according to the vehicle speed to save memory; iii) the storage is made so that measurements can be flexibly accessed. This latter attribute is of paramount importance. For example, suppose that **method 2** is chosen, meaning that the area-mean powers in the scenario depicted by Figure 1 are retrieved from the storage in the locations indicated by the dark dots, which are at the intersections of the equidistant points from the transmitter (dashed arcs) and the measurement path (solid thick line). If the arcs are traced equidistantly in the log-distance, sampling at the intersections would correspond to **method 1**.

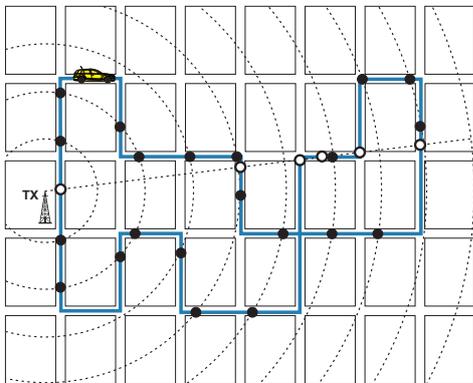

Fig. 1. Hypothetical partial aerial view of a measurement area, with equidistant points from the transmitter (dashed arcs), straight path departing from the transmitter (dashed straight line), measurement path (solid thick line), and local-mean power measurement points (dots).

Method 1 and **method 2** have been created to help deter-

mining if the scale of distances regarding the piece-wise linear fitting, which is logarithmic, should be used to determine the sampling spacing, or if this spacing should be governed by a linear scale. **Method 1** produces samples with higher spatial density at the beginning of the linear-scaled distance range, decreasing this density as the distance approaches the end of the range. **Method 2** produces sparse samples at the beginning of the logarithmic-scaled distances, increasing the sampling density as the distance approaches the end of the range.

Due to the attachment of the measurements to the time when they were gathered, it is possible to analyze the influence of time-varying whether or atmospheric conditions on the propagation characteristics of the environment. This is particularly useful in the mmWave range, in which the signal is strongly affected by rainfall. In this case, the measurement vehicle goes through the measurement path several times, at different moments of a day, or even at the same time of different days. In another situation, the local-mean received signal levels need to be analyzed along a straight line from the transmitter, in a given direction. In this case, the received powers must be read from the storage at points corresponding to the intersection of the straight line and the line associated to the measurement path, which is shown in Figure 1 by the non-filled dots. This would correspond to another sampling method in which the distance values are randomly distributed.

The segmented regression for multi-slope fitting has to be applied to spatially-correlated samples resulted from the shadowing process. However, the accuracy of the regression result is widened due to the spatial dependence among observations [36, p. 73]. This can be explained by the fact that, even for large sample sizes, the ratio between the actual number of samples N and the effective sample size N^* becomes $N/N^* = (1 + \rho)/(1 - \rho)$ [36, p. 73], being ρ the correlation coefficient between neighbor samples. Then, strictly speaking, the reduction of the effective sample size due to an increased spatial correlation widens the confidence interval on the estimated parameter or statistic. To overcome this problem, N is chosen such that neighbor samples have low correlation, using the rule-of-thumb

$$N = \left\lceil \frac{d_{\max} - d_0}{d_d} \right\rceil, \quad (5)$$

where d_{\max} is the upper limit of the transmitter-receiver distance, and d_d is the decorrelation distance that determines the degree of spatial correlation of the shadowing [14], both in meters. From this rule one can conclude that if more samples are needed for bettering the accuracy of the segmented regression in a given environment (fixed decorrelation distance), then a larger distance range must be considered.

It is also possible to improve the accuracy of the regression by taking more than one sample at each distance. For instance, if the value of N computed from (5) is not sufficient for reaching the desired accuracy, and for some reason the measurement distance range cannot be increased, an effective number of samples N' can be obtained by taking N'/N samples, on average, for each of the N distance points. The multiple samples per distance will be gathered at different locations, as illustrated by the dots on the arcs in Figure 1. In fact this

is the most used method in practice, but care must be taken so that all samples belong to an area with certain homogeneity in terms of topography and morphology. For example, one should avoid mixing samples coming from a dense urban area with samples from a rural area, unless the propagation characterization is intended to infer about the joint influence of these two environments on the multi-slope path-loss modeling.

IV. RESULTS AND DISCUSSIONS

This section presents segmented regression results using the SLM tool, whose engine function embedded in Matlab codes can be found in [37], applied to synthetic data generated by the simulation platform described in [38]. The parameters of the SLM engine function are described in [39].

Figures 2 and 3 give fitting results assuming that the local-mean powers refer to a two-slope propagation scenario with loss exponents $n_1 = 2$ and $n_2 = 4$, shadowing standard deviation $\sigma = 7$ dB, breakpoint BP = 300 m and decorrelation distance $d_d = 10$ m. The reference distance is $d_0 = 1$ m, and the end of the distance range is $d_{\max} = 1000$ m. The samples were processed with the SLM tool embedded in the two-lope fitting algorithm, and with the ordinary least squares linear regression (single-slope fitting). The number of samples is $N = 500$, with 5 samples in each of the $N = 100$ distances. Figure 2 considers equally-spaced log-distances, whereas Figure 3 considers equally-spaced linear-distances.

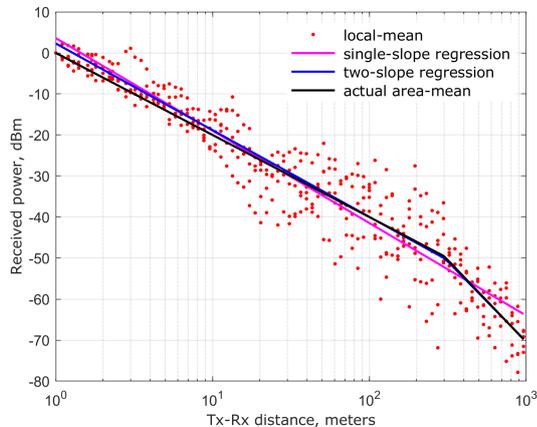

Fig. 2. Regressions to multiple measurement samples per log-spaced distances. Better viewed in color.

The parameters estimated from the scenario depicted in Figure 2 for the two-slope regression were $n_1 = 2.11$ and $n_2 = 3.91$, BP = 304.99 m, and $\sigma = 5.70$ dB, with a coefficient of determination¹ $R^2 = 0.92$, and a mean residual sum of squares MRSS = 32.41. The single-slope regression yielded $n = 2.25$, $\sigma = 5.94$, $R^2 = 0.92$ and MRSS = 35.21.

Regarding the scenario considered in Figure 3, the estimated parameters were $n_1 = 2.24$, $n_2 = 4.19$, BP = 322.35 m and

¹The coefficient of determination R^2 is the proportion of the total variability in the dependent variable that is accounted for by the regression equation in the independent variables [40]. Using the R^2 alone may be not enough for assessing the quality of the regression, since fitted curves can have a high R^2 value, but wrong regression models [29], [40]. A solution is to combine the R^2 information with the mean residual sum of squares (MRSS).

$\sigma = 6.85$ dB for the two-slope regression, with $R^2 = 0.76$ and MRSS = 46.86. The single-slope regression yielded $n = 2.91$, $\sigma = 7.18$ dB, $R^2 = 0.73$ and MRSS = 51.33.

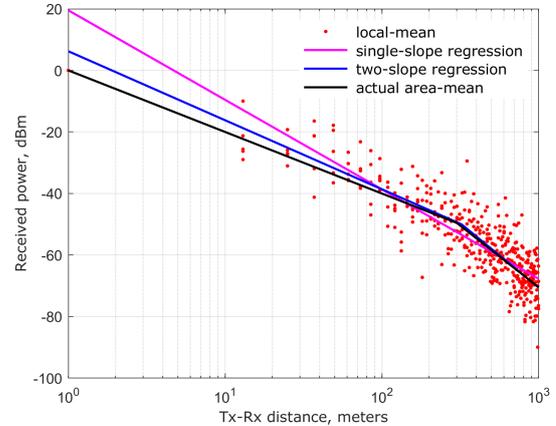

Fig. 3. Regressions to multiple measurement samples per linearly-spaced distances. Better viewed in color.

From these results it can be readily concluded that the conventional single-slope path-loss model is not capable of adequately describe the received signal power decay in the presence of a two-slope loss. The poor fits can be observed visually and by means of the R^2 and MRSS values.

It can be also noticed that samples equally spaced in logarithmic-scaled distances can produce better fits than samples equally spaced in linear scale. However, this is not a general conclusion, since the randomness of local-mean received powers, even in the same environment, turns the estimated parameters into random variables. In other words, if measurements are taken in the same region, but with the measuring vehicle traveling over different paths, different realizations of the local-mean powers would result, changing the values of the estimated multi-slope parameters. This fact leads to the need of associating other statistical metrics to the estimates, for example the confidence intervals on the loss exponents and breakpoint positions. One way of reducing variability consists of reducing the effect of measurement outliers, which can be done by means of robust and regularized fitting options of the SLM engine.

V. CONCLUSIONS

This paper presented a method for fitting local-mean signal power measurements to a non-increasing multi-slope piecewise linear function of the transmitter-receiver distance. The optimal fit was achieved by means of the shape language modeling tool when configured to the first order spline fitting option, with two and three segments. Some results were presented and discussed, and guidelines were given in what concerns the strategy for sampling the received power levels.

A future extended version of this paper could explore more test scenarios and path-loss parameters, as well as a deeper statistical analysis on the accuracy of the multi-slope path-loss modeling via segmented regression. This analysis can be

made in light of confidence intervals on breakpoints and loss exponents, as well as of regression accuracy metrics.

Another subsequent research consists of capturing real received signal power data, perform multi-slope modeling and validate path-loss prediction under this model also based on real received signal levels across the area under analysis.
